## SOME EFFECTS OF STEAM STERILIZATION ON PHYSICAL, CHEMICAL AND BIOLOGICAL RELATIONSHIPS OF SOILS.

---

### Introduction

The study of the complicated inter-relationships of soil micro-organisms (9) and plant diseases, and of soil micro-organisms and soil fertility, may be simplified by first studying the relationships of a few known organisms on sterilized soil devoid of its enormous population.

Each gram of soil commonly harbours millions of bacteria, thousands of fungi, Actinomycetes (27), some of each pathogenic to plants (7), algae, a smaller number of protozoa (8), nematodes, worms, insects, besides disease producing virus proteins, bacteriophages, mycophages, toxins, enzymes and various products of the micro-organisms including deliterious and stimulating substances. All these directly or indirectly have a bearing on plant diseases and soil fertility. The prevalence of certain organisms or the chemical changes brought about by them influence the activity of the other members of the soil microflora.

The study of the effects of known micro-organisms in sterilized soil necessitates a study of the physical and chemical-biological changes in the soil caused by sterilization, for the results may be misleading unless the changes due to sterilization are measured.

A great deal of work has been done since 1900 by various workers in England and the United States on "partial sterilization" by steam and chemicals. Their effects have been determined, so

that the findings obtained by these workers would in many cases apply to the soils as sterilized in this investigation. On the other hand, certain phases were investigated which the writer to date has not seen mentioned in soil literature.

Some physical properties of the four Alberta soils, including water relations, and chemical properties including their content of the three important plant elements, nitrogen, phosphorus and sulphur, as affected by sterilization and subsequently by microbial activities were investigated.

### Review of Literature.

In experimental work soils are sometimes partially or completely sterilized in order to destroy certain groups or all of the living organisms normally found in the soil, with the object of studying their relation to the soil. In practice soils are sterilized in greenhouses to get rid of certain parasitic fungi, bacteria, actinomycetes and other undesirable organisms. Complete sterilization in practice is not aimed at (30) for there are many organisms which are beneficial to plant growth in that they improve the fertility of the soil by such processes as ammonification, nitrification, sulfofication and general decomposition of organic matter.

Of the different methods used to sterilize soils, dry heating, hot water, electricity, steam and chemicals have been tried, but so far the use of steam still gives the best and most complete sterilization.

In using dry heat there is always a danger of overheating certain parts of soil. Such soils become infertile and seedlings turn blue and grow very slowly if they grow at all (21).

Newhall and Nixon (33) investigated the method of electric pasteurization. They developed the "Ohio type" of pasteurizer in which the soil is heated by the resistance it offers to the electric current passed through the soil by special electrodes, and the "New York type", fitted with "pipe-type" spaced heaters placed at suitable intervals to impart heat to the soil by thermal conductance. In both they used a low temperature of 70 degrees C.

Notes on the subject

In general, the soil is a mixture of organic and inorganic matter. The organic matter is derived from the remains of plants and animals which have died and decayed. The inorganic matter is derived from the minerals of the earth. The soil is a complex system, and its composition varies greatly from place to place. It is the result of a long and continuous process of weathering and decay. The soil is a living system, and it is constantly changing. It is a dynamic system, and it is always in a state of flux. The soil is a complex system, and its composition varies greatly from place to place. It is the result of a long and continuous process of weathering and decay. The soil is a living system, and it is constantly changing. It is a dynamic system, and it is always in a state of flux.

but it took 18 hours to heat up. It destroyed common plant pathogenes.

Practical sterilization is discussed by Senner (26), Bewley (21) and Newhall (30). Newhall concludes that steam sterilization leaves no toxic residues or water-logging and leaves the soil in good tilth (30).

Darbishire and Russell (34) in 1906 noted that in steam sterilized soils heated to 120 degrees C. the absorption of oxygen was greatly diminished but that in partially sterilized soils, heated to 95 degrees C., the rate of oxidation was considerably increased, due mainly to the activity of the surviving microorganisms. They studied the influence of partial sterilization, using volatile antiseptics and steaming at 95 degrees C. They found that the crop could get from heated soils three times as much nitrogen and twice as much phosphoric acid and potash as from unheated soils, and that the increase in plant dry matter was considerable. Such plants showed a higher percentage of nitrogen, phosphoric acid and potash in the dry matter. Inoculating partially sterilized soil with fresh soil caused a decreased plant growth compared to the uninoculated. This beneficial effect of partial sterilization alone extended over more than one crop so long as the new flora was left undisturbed, but by the addition of tap water the crop decreased. They believed that increased availability of the plant nutrients was connected with the modification of the bacterial flora, although they recognized that when the soils were sterilized by steam a certain amount of decomposition took place. They found that

volatile antiseptics also increased oxidation and the solubility of minerals and available phosphorus as judged by the amount taken up by the plant.

Russell and Hutchinson (11) found that heating the soil by steam to 125 degrees C. killed all the organisms present in the soil and caused a production of 5 p.p.m. of ammonia, but after that first production no further change took place. Heating by steam to 98 degrees C., or toluene, increased ammonification. For a few days there was a period of inactivation but this was followed by one of rapid change during which ammonia was produced in large quantities; lastly, a slow period of change set in and further production of ammonia was small. They concluded that organisms concerned with ammonification are not injured by heating to 98 degrees C. or by toluene but that these treatments destroy organisms which are inimical to ammonifying bacteria. Bacteria increased to great numbers following partial sterilization. This they attributed to the absence of protozoa. "Heat not only destroys the nitrifiers but brings about some change whereby the soil is rendered unsuitable for their development; they no longer act even when re-inoculated into the soil. It appears that an inhibitory substance is formed by heat." However, by the time the second crop was growing on heated soils, the nitrifying bacteria added developed abundantly, suggesting that the toxic body slowly disappears from the soil.

Lyon and Bizzell (14) found that nitrates remained low up to 14 weeks in steamed and re-inoculated soils and ammonia increased in sterilized re-inoculated and sterilized soils, due to

ammonifying bacteria from the air, since their soils were kept in sterilized fruit jars, afterwards loosely covered.

Baldwin (23) states that most of the organisms developing after partial sterilization are spore formers. Increase in ammonia is due to the activity of ammonifying bacteria, many of which are spore formers.

Waksman and Starkey (25) found that the formation of ammonia was directly dependent on the organic matter content of the soil and not correlated with increase in the numbers of bacteria when normal soils of different organic matter content were compared. Heating the soil caused bacteria to increase very markedly when re-inoculated into the soil. Toluene and heating influence greatly not only the development of bacteria and protozoa in the soil, but also that of Actinomycetes and especially fungi. They are repressed at first but soon develop, especially when re-inoculated, and reach numbers greatly in excess of those of untreated soils. Ammonia accumulates in partially sterilized soils over the unheated soils, especially in soils rich in organic matter, but in poorer soils the rapid development of fungi may lead to a partial utilization of ammonia. Coleman (31) showed that marked differences exist in the activity of fungi regulated by the type of soil and the quality of organic matter. Chemicals beneficial to one group may be detrimental to another.

Koch (22) and Cutler (28) studied protozoa. Koch concludes that active protozoa are found in the soils only at high moisture content. Cutler (28) proved that protozoa were one of the factors concerned in keeping the numbers of bacteria below the level they might otherwise have attained.

physiological reactions from the soil. These results were obtained in the laboratory, where the soil was sterilized.

Results (12) showed that soil is the primary source of

the most essential nutrients for plants. It is the source of the majority of the nutrients of which the plant is composed.

Coleman, Lent and Kopeloff (17) sterilized soils at 80 degrees C. for one hour using dry heat on successive days up to 5 days. With intermittent sterilization using a low temperature, bacteria were almost completely decimated with but a slight change in the chemical constitution of the soil as judged by water soluble solids. Sterilization by steam increased the solids 10 times.

Schreiner and Lathrop (13) in 1912 found an increase in water soluble organic matter and in acidity (probably titrable acidity) in the steamed soil. At the same time ammonia and amines were formed. They found an increase in all organic constituents isolated from soils: xanthine, hypoxanthine, guanine, cytosine, arginine, di-hydroxystearic acid.

Pickering (12) found germination and plant growth were retarded in soils heated over 60 degrees C. up to 125 degrees C. (dry heat). He found more organic and inorganic matter in the heated soil extracts and this increased afterwards with time.

Lyon and Bizzell (16) found that steamed soil on standing up to 3 months, without plants, steadily decreased in water soluble organic matter content including ammonia and other soluble nitrogenous matter. This soluble organic matter rapidly decreased for several weeks in steamed soil re-inoculated with original soil (14). Plants made much better growth on steamed soils that were re-inoculated but didn't continue at the same rate throughout the season for they were finally exceeded by plants on uninoculated steamed soils. At maturity the latter had more dry matter.

Baldwin (23) found a consistent increase in acid soluble phosphorus after sterilization but no figures are given. His determination was made on samples of sterilized greenhouse soil.

McCool, referred to by Newhall (30), found soluble manganese may be increased materially by steam sterilization. A lower water holding capacity in steam sterilized soil has been reported (30) and (12).

Various chemicals have been tried as soil antiseptics. When used in large doses they bring about almost complete sterilization for a time, but when the chemical is used up the organisms regain their activity.

Carbon bisulphide, toluene, chloroform and formalin in small doses produced conditions similar to partial sterilization (19) but mercuric chloride, copper sulphate and thymol did not increase productiveness though very small doses stimulated the activity of the microflora (34).

The use of volatile antiseptics, in partial vacuum or under a combination of heat and pressure, if repeated for three successive days would achieve complete soil sterilization without involving radical alterations in the chemical constitution of the soil (17). According to Darbishire and Russell (34), no amount of solution will bring every particle of soil in contact with the disinfectant, therefore it is reasonable to suppose that mixing a powdered chemical will not distribute it thoroughly through the soil.

Matthews (19) found bacterial numbers were increased for the first few days following application of antiseptics, the increases varying in the same direction as the molecular weight and heat of combustion of the antiseptic. After a sudden rise in numbers to the maximum there was a gradual return to normal which, she concluded, was due to the feeding effect of the antiseptic.

Aliphatic compounds gave quicker and smaller rises than aromatic, and an introduction of the methyl group into the benzene ring lessened toxicity but chlorine and the nitro group increased both toxicity and stability of compound.

Buddin (18) found phenol and its derivatives were effective if used in high enough doses. Small doses, M/200 up to M/50, caused a high rise in bacterial numbers but M/10 to M kept the soil protozoa and bacteria in an inactive condition for 75 days. Phenol, M/50 to M, keeps protozoa and bacteria inactive for 75 days. Dixon, Annie (20) studied the effects of phenol, carbon-bisulphide and heat on protozoa and found that all strengths of phenol below 1.8 percent showed the presence of protozoa in time and that heating the soil in a steamer for 30 minutes is usually sufficient to kill the protozoa. Phenol, she found, had greater lethal effect on protozoa than carbon-bisulphide.

Calcium cyanamide in small doses increased the activity of soil organisms in <sup>as</sup> partial sterilization (24), but in large doses had a depressing effect. The amount depends on the nature and hydrogen ion concentration of the soil. It controlled "damping off" and prevented the damage due to *Plasmodiophora brassicae*. Doran (32) compared formaldehyde, acetic acid and pyroligneous acid as soil disinfectants and found pyroligneous acid a cheap, safe, effective disinfectant for "damping off." Cresylic acid was as good as formaldehyde; it increased the yield, though less than steaming (21). Carbon bisulphide and formalin together gave the best and most complete chemical sterilization, but it is too expensive (30).

## Outline of Investigation

The investigation was divided into two phases, first, the physical, and second, the chemical-biological changes effected by steam sterilization in four Alberta soils: Edmonton sod, a black park loam; Vegreville cultivated, black park loam also but more sandy in texture; Gros Ventre brown prairie loam, and Fallis gray wooded silty loam. The first two soils mentioned were high in organic matter while the last one was very low in this respect.

In the study of the physical properties of these soils the non-sterilized were compared with the sterilized with respect to mechanical analysis, water holding capacity, shrinkage, sticky point, and capillary power. Since soil moisture relations affect greatly the ultimate productive power of the soil, certain differences in sterilized soils may be due to purely physical factors.

The chemical-biological phase included the study of soil acidity, nitrification, ammonification, sulfofication, easily soluble phosphorus and ammonification by pure cultures. These processes in certain ways are indicative of the microbiological activity and the productive power of the soil.

In the study of the physical properties only two treatments were compared, -- the non-sterilized with the sterilized soil. In the chemical-biological, three treatments, the non-sterilized, sterilized and sterilized re-inoculated were compared in order to determine what changes were caused by sterilization alone,

and how the microbial activity responded to these changes, as compared to normal soils.

For the study of the physical properties, the soil was sterilized when needed, in one gallon crocks. In the study of the second phase the soils were sterilized in Erlenmeyer flasks and incubated in a dark control chamber at room temperature (23 degrees C. to 27 degrees C.)

Two nitrification experiments were conducted. The first was started in the fall of 1936 and carried on for 12 weeks. Nitrates were determined one day after setting up the experiment, then every 2 weeks for 12 weeks. The second, started in April 1937, was carried on for 39 weeks and nitrates were determined at the end of 6 days, 6 weeks, 12 weeks, 14 weeks ----- 39 weeks.

The plan followed was the same in both. In the first, a total of 84 (200 cc.) flasks, each containing 50 grams of soil (water-free basis), were incubated. This consisted of 7 flasks of each treatment, making 21 flasks of each soil, namely, 7 of non-sterilized, 7 sterilized and 7 of sterilized and re-inoculated with one per cent of the original soil. One flask of each treatment was taken out for each determination. Duplicates were taken out of the same flask in order to decrease the amount of apparatus required.

The second nitrate experiment was made up of 88 (200 cc.) flasks and 44 tumblers incubated as in the above experiment. The sterilized and the sterilized re-inoculated were incubated in flasks while the non-sterilized were incubated in tumblers with

perforated covers. This experiment was made up of 11 samples of each treatment for each soil. For each determination one flask or tumbler was taken out and duplicates taken from it. Nitrates were determined in the second experiment right after sterilization, then at the end of 6 days, 6 weeks, 12, 14, 16, 18, 20, 26, 30 and 39 weeks.

The ammonification experiment was outlined following the same plan. A total of 120 (200 cc. Erleumeyer) flasks, each containing 50 grams of soil (water-free) were incubated as above. This experiment included 30 flasks of each soil, that is 10 flasks of each treatment. Ammonia was determined 3 days, 6 days, 2 weeks, 4, 6, 8, 10, 12, 16 and 20 weeks after setting up the experiment. Before determining ammonia, 2 grams of soil (water-free) out of each flask were taken for easily soluble phosphorus determination.

In the sulfification experiment 3 treatments of each of the 4 soils were again included. A total of 168 samples (each 100 grams water-free) were incubated, one-third of them in tumblers and two-thirds in flasks with cotton plugs as for nitrates and ammonia. The flasks contained the sterilized and the sterilized re-inoculated soils. Out of the 14 samples of each treatment, 2 were taken out each time for analysis, duplicates being taken from separate flasks and tumblers. Water soluble sulphates were determined right after sterilization and upon 2 weeks, 4, 8, and 12 weeks incubation.

In the experiment with pure cultures of *Ophiobolus*, an antagonistic fungus (no. 32), and a non-antagonistic fungus (no. 3), 36 flasks of Edmonton sod were sterilized and 12 in-

oculated with each organism. These were incubated in a dark control chamber at a temperature of 23 to 27 degrees C.

## Methods

---

Soil samples, collected in the summer of 1936, were air-dried and stored in large glass containers in the laboratory. These glass containers were replenished from time to time as needed with soils brought in from the shed where the bulk of each sample, except the Edmonton, was stored, while in the case of the Edmonton soil a second sample was taken from the same field in the fall of 1937.

All soils were put through a 2 mm. sieve before setting up any experiment, to secure uniformity by excluding extraneous matter, roots, stones and especially coal-like inert matter from Fallis gray wooded soil.

Before sterilization the soils were brought to optimum moisture and allowed to stand half an hour to one hour to thoroughly wet the particles, except in the capillary experiment when the soils were moistened for two days before sterilization.

The optimum moisture used for Edmonton black park soil was 36 per cent; for Vegreville black park soil 30 per cent; for Gros Ventre brown prairie soil 22 per cent and Fallis gray wooded 19 per cent.

Table I shows the hygroscopic moisture, optimum moisture and a few other physical characters of the soils worked with.

Sterilization was done by steaming the soil once for 45 minutes at full pressure (15 to 17½ pounds of steam) in the autoclave, cooling one day and sterilizing the second time, for

30 minutes again at full pressure (approximately 120 degrees C.)

After sterilization the soils were cooled and half of the sterile flasks were re-inoculated with  $\frac{1}{2}$  per cent to 1 per cent of the original soil for nitrification, ammonification and sulfification experiments. In other experiments where the sterilized soils were compared with the non-sterilized soils for physical properties and for phosphorus without incubation, no re-inoculation treatments were included.

For mechanical analysis, <sup>u</sup>Boyoucos method (1) was used, but instead of starting with oven dry soil, as would ordinarily be done, moist samples were weighed. This was done because, in order to sterilize the soil properly without overheating at the bottom or along the sides of the container, and thereby causing drastic changes, the soil must be quite moist; therefore, all soils were brought to optimum moisture prior to autoclaving. The non-sterilized soils had the same amount of moisture added as the sterilized, and were kept moist for the same length of time. It was thought that following sterilization, drying may affect the soil colloidal content, and thereby alter changes induced by steam; therefore, moist samples were worked with. Moisture was determined on separate samples and all calculations were based on water-free weight. Since it was much more difficult to weigh accurately moist samples, due to the rapid loss of moisture, a greater error had to be contended with. To each sample 5 cc. of sodium oxalate and sodium silicate were added. All soils were stirred for 15 minutes except Fallis soil which

was stirred for 20 minutes; in other respects the usual procedure was followed.

Some seven determinations were made by the pipette method, which consisted of drawing out aliquots of 20 cc. after settling for 50 seconds, from a depth of 10 cms. below the surface of the liquid in the "Bouyoucos" cylinder; after 98 seconds from a depth of 20 cms., and after 80 minutes from the same depth. These aliquots were evaporated in small dishes at 100 degrees C., cooled and weighed and the percentages of clay, silt, and sand computed by difference.

Real specific gravity was found on 10 grams of oven dry soil weighed in a 25 cc. volumetric flask filled with water to the mark.

$$\text{Real specific gravity} = \frac{\text{Weight of soil in grams}}{\text{Volume of soil in cc.}}$$

Water holding capacity was found by the funnel method using 50 grams of soil. Readings were taken when drainage stopped. In certain determinations readings were made at 15 minutes, 1 hour and 2 hours.

Shrinkage was determined by a modification of Haines (2) method, by displacement of mercury. The soils were brought to optimum moisture, half of each was sterilized twice in the manner mentioned, then both the non-sterilized and the sterilized soils were air-dried and passed through a 100 mesh sieve. Capillary moisture still retained was determined. Into 50 grams (air-dry) soil placed on a glass plate, a measured amount of moisture from a graduated cylinder was incorporated by

was written for 21 December; it is a very short letter.

means of a spatula until the sticky point was almost reached. It was then kneaded, shaped by hand and moistened more especially at the ends, to prevent cracking. The wet soil cylinder was weighed and its volume determined by placing it in a glass centrifuge tube, held erect, and then filling the tube with mercury and levelling off with a microscope slide. The buoyant effect was overcome by placing a perforated rubber stopper below the level of mercury. Weight and volume of the soil cylinder were measured at intervals of drying first at room temperature, later in an oven at 100 degrees C. and finally after oven drying for 2 days at 110 degrees C. All data were reduced to the basis of 1 cc. oven dried soil. Some difficulty arises, using this method, in finding the first volume if the soil cylinder is too wet, as the buoyant force of mercury compresses the soil and distorts the soil cylinder; also, small bubbles of air often adhere. But with a little drying these difficulties can easily be overcome and the volume measured accurately.

The sticky-point was determined on the four sterilized and non-sterilized soils by a somewhat arbitrary method. Air-dry 50 gram samples were moistened with a measured amount of water and the moisture worked into the soil with a spatula, on a glass plate as for shrinkage, until the sticky-point was nearly reached. This was judged by the appearance of wetness. Then the wet soil was kneaded by hand and a little more moisture worked into it until the soil became sticky as judged by the adhesion to the palm of the hand and the force required to tear away the soil cake after squeezing in the hand.

Capillary rise in the four sterilized and the non-sterilized soils was determined by the ordinary method. Glass tubes 3 to 4 feet long,  $1 \frac{1}{6}$  to  $1 \frac{1}{8}$  inches in diameter, wrapped at one end with four plies of cheese cloth, were filled with soil and immersed vertically in a pan containing water maintained at a constant level. The soils were brought to optimum moisture, allowed to stand two days to become uniformly wet, and the lost moisture was made up. Half of each soil was sterilized as described above, then all the soils were spread uniformly on paper to dry for 5 days. Moisture was determined before the tubes were filled. The soils were put through a 2 mm. sieve and the large granules broken up gently. The tubes were filled by pouring the soil through a funnel suspended at a uniform height, care being exercised to secure an even distribution of the large and small soil particles. The soil was packed by tapping gently the sides of the tubes with a rubber pestle until the soil column moved down a definite distance (approximately  $3\frac{1}{2}$  inches). From the time water was added readings of the capillary rise above the water level were taken at 5 minutes, 15 minutes, 1 hour, 2, 3, 4, 12 and 24 hours and thereafter every day for 42 days, and at the longer intervals until 61 days from the start.

The pH values were determined by the quinhydrone electrode method. One day after sterilization, moist samples equivalent to 5 grams of water-free soil were diluted with 20 cc. of distilled water and pH values read at 1, 5, 15 and 30 minutes.

Water soluble phosphorus was determined colorimetrically on

1:5 water extracts of soil filtered through Berkefeld filters by Parker's method (3). Moist samples equivalent to 50 grams water-free soil were extracted for one hour on a shaker and 25 or 50 cc. filtrate evaporated in porcelain dishes to which 1 cc. of 10 percent  $\text{Mg}(\text{NO}_3)_2$  was added. Organic matter was oxidized and ignited off in the electric muffle. The ash was dissolved with 1:20 HCl, made up to required volume and read with ammonium sulphuric acid molybdate and stannous chloride according to the usual procedure. A few samples were determined without ignition, in which case the same procedure was followed in that all reagents were added in the same amounts as for the above only that  $\text{Mg}(\text{NO}_3)_2$  was oxidized first and ignited off before the filtrates were evaporated.

Easily soluble phosphorus (acid soluble at pH 3.0) was determined colorimetrically by Truog's (4) method. Moist samples of soil equivalent to one gram water-free were extracted by shaking one hour, with 200 cc. buffered pH 3.0 sulphuric acid solution, adjusted when necessary by the addition of 1 to 7 drops of N sulphuric acid in order to maintain this reaction. The pH values were read before and after extraction with the potentiometer. A few soil extracts after filtering through paper were highly colored and such were cleared by means of activated charcoal. Using 25 cc. filtrate, blue color was developed with ammonium molybdate sulphuric acid solution and stannous chloride.

Easily soluble phosphorus upon incubation was determined on soils taken from the flasks incubated for ammonification just before determining ammonia. The flasks were weighed up and

brought to optimum moisture, if they had lost any moisture, cultivated thoroughly and duplicate moist samples equivalent to one gram (water-free) soil were weighed out for phosphorus analysis and put into stoppered shaker bottles for later determination. Some difficulty in weighing moist samples was encountered due to rapid drying. This was partly avoided by making rapid weighings.

Nitrates were determined colorimetrically by the phenol-disulphonic method as modified by H. J. Harper (5) in which one to five water extractions were analysed.

Ammonia was determined by the McLean and Robinson (6) method of leaching 25 grams of soil with 500 cc. N. sodium chloride solution and distilling the soil extract with magnesium oxide, collecting ammonia in standard acid and titrating the excess with a standard base using M.R. Distillation was carried on for  $\frac{3}{4}$  to 1 hour until approximately 250 cc. distillate were collected.

To find if the magnesium oxide added in the first distillation upon standing one day in the solution had a breaking down effect on the dissolved organic matter, thus further liberating ammonia, 200 cc. of distilled water were added and a second distillation was carried out.

Water soluble sulphates were determined gravimetrically by precipitation as barium sulphate. Extractions were made by shaking for one hour 100 grams of soil with 250 cc. of water in the first two determinations, and with 500 cc. in all the others. The soil extracts were filtered through Berkefeld filters, evaporated to dryness with  $\text{Mg}(\text{NO}_3)_2$  and ignited in an electric muffle

at 600 degrees C. for  $\frac{1}{2}$  hour.

In the pure culture experiment ammonia was determined by the same method referred to above, that of McLean and Robinson.

In all cases where the soil was incubated, the flasks were taken out of the chamber every week or ten days, weighed and the loss of moisture determined. The flasks were watered with sterile water by means of a sterile pipette, flaming the mouth of the flask each time the cotton plug was removed. By means of a stirring rod which was placed in each flask through the cotton plug, the soils were cultivated after being watered. It was found difficult to keep the cotton plugs in good condition, especially after prolonged incubation they became loose.

## RESULTS AND DISCUSSION.

### PHYSICAL: Mechanical Analysis.

Mechanical analyses were made on 25 samples, of which the results of 16 are represented in graph 1 and illustrative data are supplied for each soil in table 2. They show the trends obtained when sterilized and non-sterilized soils are compared.

According to graph 1, taking the silt limits as 0.002 mm. to 0.05 mm. in diameter of particles, the Edmonton black park soil should be classed as loam to silt loam, the Vegreville black park soil as sandy loam (probably fine sandy loam), the Gros Ventre brown prairie soil as loam, and the Fallis gray wooded soil as silt loam.

Negative results were obtained with respect to the differences between sterilized and non-sterilized, at least down to 0.002 mm. in diameter of particles.

With the pipette method somewhat lower percentages were obtained for silt, lower for clay, and somewhat higher percentages for the sand fractions.

Table 1 - Physical characters of the four Alberta soils.

Graph 1. Mechanical analysis of non-sterilized and steam sterilized Edmonton and Vegreville black park soils, Gros Ventre brown prairie soil, and Fallis gray wooded soil.

1. The first thing I noticed when I stepped out of the plane was the cold. It was a sharp contrast to the warm, humid air of the tropics. I shivered as I walked down the stairs, my hands tucked into my pockets. The ground beneath my feet was hard and uneven, a mix of dirt and gravel. I looked up at the sky, where a few wispy clouds were scattered across a pale blue expanse. The sun was high, casting a bright, harsh light over the landscape. I felt a sense of isolation, a feeling that I was alone in a vast, unfamiliar world. The silence was deafening, broken only by the distant hum of an engine or the occasional cry of a bird. I took a deep breath, the cold air filling my lungs. I knew this was just the beginning of my journey, and I was determined to see it through to the end.

### Water Holding Capacity.

Most of the work on water holding capacity of sterilized and non-sterilized soils was done with Edmonton soil although the other three soils were tried. Table 3 illustrates the type of results obtained, using the funnel method. The averages of 16 determinations with each treatment of Edmonton soil were 72 percent for the sterilized and 73 percent for the non-sterilized soil. These figures are not included in table 3. The figures that appear in table 3 for Edmonton soil were obtained in a subsequent determination using another batch of sterilized soil. The results show that the sterilized soil has a slightly lower water holding capacity, but the differences were not very definite and were not obtained in every case. The variation between different determinations was often more than 4 percent, therefore the differences found cannot be taken as significant. Newhall (30) and Pickering (12) report that sterilized soils have a lower water holding capacity, but they also hold water for a longer time (12).

Table 3 - Percent water holding capacity of the four Alberta soils.

### Shrinkage.

The results of the shrinkage experiment are represented by graphs 2 and 3, and data are supplied in table 4. They show that during the early stages of drying there was a decrease in the volume of the soil, proportional to the amount of moisture lost.

This decrease, represented graphically, is shown by the slant of the curve at an angle of approximately 45 degrees to the abscissa. It is indicated well in graph 3 in Fallis soil in the non-sterilized, from 0.45 cc. to 0.35 cc. moisture content per cc. of soil; and in the Fallis sterilized from 0.45 cc. to about 0.33 cc. of moisture. The same trend is shown by Gros Ventre soil from 0.6 cc. to 0.45 cc. loss in moisture by the non-sterilized, and from 0.61 cc. to 0.48 cc. by the sterilized. No doubt a sharper break would have been obtained had another reading been taken at about 0.4 cc. loss of moisture per cc. of soil.

Examination of graph 2 shows the same trend, but for a short distance; in the Edmonton soil from 0.75 cc. to 0.6 cc. and possibly to 0.4 cc. loss of moisture by both the non-sterilized and sterilized soil. Vegreville non-sterilized follows this trend from 0.8 cc. to 0.55 cc. and possibly to 0.5 cc. of moisture per cc. of soil.

There was a sudden change in the direction of the curves in Fallis soil from 0.35 cc. moisture in the non-sterilized and 0.33 cc. in the sterilized up to the last stage of drying. The curves become almost parallel to the base (abscissa). This stage of drying is accompanied by a large loss in moisture but hardly any shrinkage in volume; at least the volume of moisture lost far

exceeds the change in volume of soil. This "residual" shrinkage in the non-sterilized Fallis amounted to approximately 0.02 cc. decrease in volume for 0.35 cc. of moisture lost, and in the sterilized approximately 0.025 cc. for 0.33 cc. of moisture lost.

The break between the "normal" shrinkage and the "residual" shrinkage is not so sharp in the Gros Ventre soil; probably it would have been, had a reading been made at about 0.37 cc. moisture content per cc. of soil. However, taking the points plotted at 0.23 to 0.25 cc. of moisture, which is well in the region of the residual shrinkage for this soil, the volume of the soil, at 0.24 cc. of moisture in the non-sterilized is approximately 1.02 cc., while in the sterilized at the same moisture content it is approximately 1.03 cc. to 1.04 cc. Again this is a very small difference, but the shrinkage is greater in the sterilized soil.

In graph 2 the Vegreville soil shows a more gradual change instead of a sharp break. This is indicated by the points plotted between 0.1 cc. and 0.65 cc. of moisture in the sterilized, and between 0.15 cc. and 0.56 cc. in the non-sterilized. A slightly greater shrinkage of about the same magnitude as in the previous two soils appears in the case of the sterilized soil, below a moisture content of approximately 0.25 cc.

The Edmonton soil shows the same trends as the Vegreville soil discussed.

From graphs 2 and 3 it appears that "residual" shrinkage is smallest in Fallis gray wooded soil and greatest in the Edmonton soil with the Vegreville following. This indicates that soils high in organic matter differ from the gray wooded soil which is low in this respect, and agrees with the findings of Haines (2)

extends for some distance in the direction of the  
in the non-stabilized soil is found to be approximately 1.5% of  
the volume for a 1.5% of water loss, and in the  
stabilized soil is approximately 0.5% of the volume for  
the same loss. The difference between the "natural" and the "stabilized"  
soils is not as large as the loss of water loss; probably it  
would have been, had a testing been done at about 0.5% of water  
content per cc. of soil. However, taking the water content of  
0.5% of water loss, which is still in the region of the  
natural soil, the loss of water is 0.5% of the soil, at 0.5%  
of water loss in the non-stabilized soil is approximately 1.5% of  
the soil in the stabilized soil the same water loss is approx-  
imately 1.5% of the soil. Again this is a very small dif-  
ference, but the difference is greater in the stabilized soil.  
In section 5 the water loss is about 1.5% of the soil content  
loss of a small amount. This is indicated by the water  
lost between 0.1% and 0.5% of water loss in the soil, and  
and between 0.1% and 0.5% of the non-stabilized soil.  
slightly greater surface of about 1.5% of water loss in the soil  
between the soil content in the case of the stabilized soil  
below a surface content of approximately 0.5% of  
the soil content is about the same as the water loss  
soil content.  
From Figure 1 and 2 it appears that the water loss in the soil is  
not as large as the water loss in the soil. This is indicated by the  
soil with the water loss content. This indicates that the  
loss in the soil is not as large as the water loss in the soil which is  
low in this content, and agrees with the results of Figure 1 (2)

who worked with Rothamsted soils, that the highest "residual" shrinkage of 18.2 percent was found in peat soil at 50.5 percent moisture content, and only 2.2 percent in the Rothamsted loam at 18.7 percent of moisture.

When these soils are compared for the differences in shrinkage effected by sterilization, slightly greater shrinkages were found in almost all soils in the case of the sterilized, but when these differences are statistically analysed they are found to be hardly significant.

The expression "based on 1 cc. water-free soil" has been used in the above rather loosely. Actually the 1 cc. of water-free soil included some air in the pore spaces between the oven dried soil particles.

Likewise, for example, the term 1.1 cc. soil volume actually would mean the volume which the soil and air and water occupied; that is, the wet volume of the soil measured, divided by the volume the same amount of soil occupied when oven dried.

Graph 2. Shrinkage of non-sterilized and steam sterilized Edmonton and Vegreville black park soils.

Graph 3. Shrinkage of non-sterilized and steam sterilized Gros Ventre brown prairie soil and Fallis gray wooded soil.

### Sticky Point.

The "sticky point" appears to be reached at a lower moisture content in the sterilized soils than in the non-sterilized. The "sticky point" was reached when Edmonton non-sterilized soil was brought to 60 percent moisture content (air-dry basis) and sterilized was brought to 58 percent.

Vegreville, Gros Ventre and Fallis non-sterilized showed the sticky points at 52, 50 and 33 percent respectively, and the sterilized at 48, 46 and 33 percent of moisture.

It was found that at 39 percent and 41.5 percent moisture, Edmonton sterilized was more sticky than the non-sterilized of the same moisture content.

In cultivating the soils in the flasks incubated for nitrification, it was observed that those which were kept sterile for a long time became quite sticky upon addition of water to bring the soils to optimum moisture, while the non-sterilized and the sterilized re-inoculated, with the same moisture content (flasks were all weighed for optimum moisture when the experiment was set up), were not inclined to become sticky.

### Capillary Rise.

Table 6 and graphs 4 and 5 show the results of the capillary experiment. Consistent and definite differences were found. In all cases the capillary rise after the first twelve hours was greater in the non-sterilized soils.

Differences became apparent even after 15 minutes in Fallis and Gros Ventre soils and after one hour in Vegreville soil. One sample of Edmonton non-sterilized soil also showed a greater rise after one hour but one of the duplicates was sluggish at the beginning and remained as low as the sterilized up to 24 hours.

The most rapid rise took place in Gros Ventre up to 4 hours but at 12 hours Fallis non-sterilized rose highest of all and remained so till the end.

The highest rise at the end of the experiment was found in Fallis soil for both the non-sterilized and the sterilized treatments. Of the non-sterilized, the next highest rise took place in Edmonton soil, a lower rise in Vegreville soil and the lowest in Gros Ventre. Of the sterilized treatments, the rise was in the same order although in none of them was the rise as high as in the non-sterilized soils.

Capillary movement ceased in 3 days in Gros Ventre and in Vegreville soils that were sterilized, but persisted very slowly even after 2 weeks in the other two soils.

Of the possible explanations for these differences one may say that temperature did not enter as a factor since all the soils were under the same conditions after sterilization. The experiment was conducted at room temperature, which did not vary

## EXPERIMENT 2

Series 4 and Series 5 and 6 show the results of the soil  
experiment. Damaged and killed off-sets were found.  
All cases the highest rise after the first level from the  
center to the center of the soil.

Disturbance between the soil and the soil is very  
and the water level and water one foot in the soil.  
and is an important one. The soil is very dry and  
after one foot and one of the disturbed and killed off the  
plant and the soil is not as the soil is not as the soil.

The most soil in the soil is one foot and one foot  
and at 15 hours the soil is very dry and the soil  
remains to all the soil.

The highest rise at the end of the experiment was found in  
the soil for both the non-disturbed and the disturbed  
series. Of the non-disturbed, the soil is very dry and  
in the soil, a lower rise is found in the soil and the soil  
is very dry. At the highest rise, the soil is very dry and  
the soil is very dry in the soil and the soil is very dry  
in the non-disturbed soil.

Generally movement found in 3 days in the soil and in  
the soil soil soil soil soil soil soil soil soil soil soil  
even after 3 weeks in the soil soil soil soil soil soil.

Of the results of the soil soil soil soil soil soil soil soil  
any soil soil soil soil soil soil soil soil soil soil soil  
soil were under the same conditions after the soil soil soil  
experiment was conducted in the soil soil soil soil soil soil.

very much, so that the differences were not caused by changes in viscosity of water.

Regarding the structure: compacting was uniform and granulation was the same insofar as the soils were all passed through the same sieve. What differences in structure existed were mostly due to the nature of the soils and to those changes induced by sterilization.

Differences in the rise of different soils would be due to texture. For example, Fallis soil is silty in nature and showed the most rapid and the greatest rise, while Edmonton soil was slow at the start because of its more colloidal nature.

It would appear that the lower rise in sterilized may be explained on the basis of soluble organic matter and salts to some extent, the content of these being increased by steam sterilization. Lyon and Bizzell (14) found water soluble matter was increased by steaming. Pickering (12) found total solids in the soil extract increased in steamed soil. But this alone would hardly be sufficient to account for such big differences, as the increases in water soluble matter or total solids are not so very great.

Comparing the capillary rise in sterilized with that in the non-sterilized soils after 58 days, the sterilized treatments of Edmonton, Vegreville, Gros Ventre and Fallis soils showed only 50.7, 38.0, 46.5 and 62.9 percent of the capillary rise in the corresponding non-sterilized soils. That is to say, sterilization decreased capillary rise by 49.3, 62.0, 53.5 and 37.1 percent respectively.

These differences cannot be attributed to initial moisture content, for a moisture determination made on a portion of the

samples used in setting up this experiment showed 4.0, 3.5, 2.5 and 1.6 percent respectively in Edmonton, Vegreville, Gros Ventre and Fallis non-sterilized soils; and 3.8, 3.4, 2.9 and 1.3 percent in the sterilized soils. Therefore, they had the same initial moisture content. Differences in the thickness of the water films, however, may exist due to the tightly held water of hydration of the salts and colloids remaining even after the hygroscopic moisture was driven off. Therefore, differences in the thickness of the water films might account in part for the differences in capillary rise between the sterilized and the non-sterilized soils.

In almost all the work there was a marked difference observed in the color of the soil extracts following sterilization. The sterilized soil extracts appeared darker in color and often colloidal filtrates which were hard to clear up were obtained, indicating that in the capillary experiment colloidal material also probably tended to reduce the rise.

Graphs 4 & 5. Capillary rise in non-sterilized and steam sterilized Edmonton and Vegreville black park soils, Gros Ventre brown prairie soil and Fallis gray wooded soil.

CHEMICAL-BIOLOGICAL.pH. Values.

Schreiner and Lathrop (13) in 1912 found an increase in total soil acidity when they steam sterilized the soil for 3 hours at 135 degrees C. They probably did not determine the hydrogen ion concentration but titrable acidity.

In this investigation, as shown by table 7, no significant differences were found in pH values between sterilized and non-sterilized as measured by the quinhydrone electrode, when the soils were steam sterilized twice, on successive days, once for three quarters of an hour and the second time for half an hour at 120 degrees C.

### Water Soluble Phosphorus.

Water soluble phosphorus in sterilized soils is increased as shown in table 8. By comparison with the non-sterilized soils the amounts were found to be 2.8 times in the Edmonton black soil, 1.7 times in Vegreville soil, 2.1 times in Gros Ventre brown prairie soil, and a slight increase in Fallis gray wooded soil.

Without ignition of organic matter dissolved in the water extracts, the amounts of water-soluble phosphorus were found to be approximately half as great.

The change induced by sterilization in water soluble phosphorus content was large in the soils high in organic matter, and relatively small in the Fallis soil, suggesting that organic phosphorus compounds are partly broken down or in some way made more soluble and are later broken down by ignition.

Schreiner and Lathrop (13) found that steam sterilization affected solubility of soil constituents: "By heating there was an increase in all of the constituents isolated from the unheated soil except nucleic acid", and "By the process of heating there was formed xanthine, hypoxanthine, guanine, cytosine and arginine when not previously existing. These products are decomposition products of nucleic acid and protein material and are all beneficial to plant growth."

Water Soluble Phosphorus

Water soluble phosphorus in fertilized soils is increased as shown in Table I. In comparison with the non-fertilized soil the samples were found to be 2.5 times in the phosphate plant soil, 1.7 times in the available soil, 1.1 times in the water soluble soil, and a slight increase in water in the water. Without addition of organic matter dissolved in the water extracts, the amount of water-soluble phosphorus was found to be approximately half as great.

The amount induced by fertilization in water soluble phosphorus content was large in the soils rich in organic matter, and relatively small in the fallow soil, suggesting that organic phosphorus compounds are partly broken down or in some way made more soluble and are later washed down by irrigation.

Conover and Latham (1951) found that steam sterilization effected reduction of soil concentration: "By heating soils and an increase in all of the concentrations isolated from the untreated soil except available soil", and the process of heating these was found to reduce, available, phosphate, and organic when not previously existing. These results are in accordance with the results of available soil and organic matter and the increase in plant growth.

### Easily Soluble Phosphorus.

Table 9 shows the quantities of easily soluble phosphorus in the non-sterilized, sterilized and sterilized re-inoculated (with original soil) four Alberta soils, throughout the incubation period of 20 weeks following sterilization.

In general, the trend, especially in the black Edmonton and Vegreville soils, seems to be that greater quantities of easily soluble phosphorus are found in the sterilized and sterilized re-inoculated than in the non-sterilized soils, but the increases are very small. While close agreement was obtained in reading the duplicates of a single determination, a variation of 10 parts per million of phosphorus was often found on separate determinations.

However, taking the averages for each treatment of each soil, over the whole period of incubation, and comparing the averages thus obtained, it appears that sterilization and incubation have increased the content of easily soluble phosphorus.

The increases of sterilized over non-sterilized found in each soil, comparing the final averages (the figures in the last right hand column of table 9, worked out on a percentage basis) were 37.2 percent in the case of Edmonton, 12.5 percent in Vegreville and 7.9 percent in Fallis soils. No significant difference was found in Gros Ventre soil though the sterilized was approximately 2 percent higher. The sterilized re-inoculated were still higher than the sterilized alone but only by 4.8 percent, 4.5 percent and 3.4 percent in Edmonton, Vegreville and Gros Ventre soils.

## Physical Properties

This is a brown, granular, crystalline solid, soluble in water, and insoluble in alcohol, ether, and benzene. It is a non-toxic, non-flammable, and non-corrosive substance. It is a white, crystalline solid, soluble in water, and insoluble in alcohol, ether, and benzene. It is a non-toxic, non-flammable, and non-corrosive substance.

In general, the physical properties of this substance are similar to those of other crystalline solids. It is a white, crystalline solid, soluble in water, and insoluble in alcohol, ether, and benzene. It is a non-toxic, non-flammable, and non-corrosive substance.

The physical properties of this substance are similar to those of other crystalline solids. It is a white, crystalline solid, soluble in water, and insoluble in alcohol, ether, and benzene. It is a non-toxic, non-flammable, and non-corrosive substance.

The increase with time of incubation might be attributed to the greater microbiological activity in the non-sterilized and sterilized re-inoculated soils, following re-moistening and cultivation, resulting in a greater production of acids including carbon-dioxide from the activity of the micro-organisms, which would form carbonic acid and act on the inorganic as well as the organic phosphorus compounds of the soil thereby bringing more easily soluble phosphorus into solution. The micro-organisms very likely utilize certain phospho-proteins and cause an accumulation of phosphorus as a by-product. But the sterilized soils also increased in easily soluble phosphorus. The increases here cannot be attributed to microbial activity, unless all soils became contaminated following sterilization. It is possible that some flasks were contaminated since they were opened to be watered once every week or ten days, but aseptic technique was used, so any contaminations would be purely accidental and it is unlikely that all the flasks were contaminated. Besides, increases in the sterilized treatments were found even right after sterilization so that these must be attributed to the changes brought about by sterilization. Heating would tend to hasten the decomposition of the soil in the same way as weathering over a long period of time. It would tend to decompose some organic and possibly inorganic phosphorus compounds of the soil. Heating combined with moistening would tend to dissolve the phosphorus contained in the inner structure of the soil particles and drying might crystallize it on the outer shell of the soil particles, thereby increasing the amount of

easily soluble phosphorus.

Baldwin (23) found more easily soluble phosphorus in sterilized soil in the greenhouse. Darbishire and Russell (34) found that plants grown on sterilized soil utilized about twice as much phosphorus as those plants grown on normal soil, and that the percentage of phosphorus in the plant grown on sterilized soil was much higher than that on the normal soil.

The first column in table 9 shows the easily soluble phosphorus in the non-sterilized and sterilized four Alberta soils, right after sterilization. These figures were obtained on samples brought into the laboratory in the fall of 1936. The rest of the figures in table 9 were obtained from the samples incubated for ammonia, which experiment was set up in the fall of 1937 when a fresh supply of soil was brought in. The figures in the first column are the averages of several different determinations. That is to say, the non-sterilized, Edmonton, Vegreville, Gros Ventre and Fallis figures are averages of 15, 6, 6 and 5 separate determinations, in which the average deviations were 1.1, 2.0, 3.5, 1.6 p.p.m., and the sterilized are averages of 15, 6, 6, 3 determinations, with an average deviation of 2.1, 2.1, 1.5, 1.5 p.p.m. respectively.

Increases in the sterilized over those in the non-sterilized in easily soluble phosphorus were found to be 22, 31, 11 and 13 percent respectively in the Edmonton, Vegreville, Gros Ventre and Fallis soils.

early column specimens.

Column (33) found were early column specimens in a few  
places only in the specimens. Column (34) found  
that plants from the specimens will differ from those of the  
specimens in those plants from the specimens. The first  
specimens of specimens in the plants from the specimens will  
be much larger than that of the normal will.

The first column in table 9 shows the early column spec-  
imens in the un-sterilized and sterilized four column will.  
right after sterilization. These figures were obtained in samples  
brought into the laboratory in the fall of 1950. The rest of the  
figures in table 9 were obtained from the samples introduced for  
analysis, which experiment was set up in the fall of 1951 when  
a first sample of will was brought to. The figures in the first  
column are the averages of several different determinations.  
That is to say, the non-sterilized, sterilized, and  
control and table 9 figures are averages of 10, 10, and 10  
determinations, in which the average deviation was 0.1, 0.1,  
0.1, 0.1, 0.1, and the standard deviation was 0.1, 0.1, 0.1,  
0.1, 0.1, with an average deviation of 0.1, 0.1, 0.1, 0.1,  
0.1, respectively.

Figures in the sterilized column in the non-sterilized  
is easily easily compared with those of 0.1, 0.1, 0.1 and 0.1  
percent respectively in the non-sterilized, sterilized, and control  
and table 9.

### Nitrification.

The results of the two nitrification experiments are shown together in table 10 and in graphs 6, 7, 8 and 9.

Greatest nitrification occurred in Vegreville and Edmonton soils, less in Gros Ventre, and least of all in the Fallis soil; that is to say the higher the organic matter content of the soil, the greater the nitrification.

In all cases the sterilized treatments remained very low in nitrates even after 39 weeks of incubation. Edmonton soil in this treatment varied from about 5 to 3 p.p.m.; Vegreville 49 to 39 p.p.m.; Gros Ventre 9 to 2 p.p.m. and Fallis 5 to 1 p.p.m., with a slight decline towards the end of the incubation period.

There was no evidence that nitrates disappear from the soil to any great extent due to sterilization. The first column in table 10 shows that in Gros Ventre and Fallis soil, nitrate content was the same before as after sterilization, while Vegreville soil, which had a high content of nitrate to start with, did show a small decrease of 5 or 6 p.p.m. of nitrate nitrogen. If nitrates disappear to a slight extent it probably is due to the heat effect causing nitrate to evaporate or change to a form which would not be measured by the phenol-di-sulfonic method.

All of the non-sterilized soils gradually accumulated nitrates. The most rapid change took place up to 20 weeks. At the end of 39 weeks, Edmonton non-sterilized contained 294 p.p.m. of nitrate nitrogen, Vegreville 239 p.p.m., Gros Ventre 219 p.p.m. and Fallis soil the least, only 85 p.p.m. These were all lower than the corresponding sterilized re-inoculated after approximately

10 weeks but higher in all cases up to 10 weeks incubation.

The re-inoculated treatments after about 10 weeks showed a much greater nitrate accumulation than the non-sterilized.

Edmonton sterilized and re-inoculated exceeded the non-sterilized by 133 p.p.m., Vegreville by 231 p.p.m., Gros Ventre by 39 p.p.m. and Fallis soil by 2 p.p.m. of nitrate nitrogen after 39 weeks.

This distinct change at 10 weeks is best seen by referring to graphs 6, 7, 8 and 9 and seems significant since a reverse change took place in ammonification, although slightly earlier. Either the nitrifying organisms (*Nitrosomonas* and *Nitrobacter*) take a long time to become active when re-inoculated into sterilized soil, or sterilization has in some way altered the chemical composition of the soil making it unfavorable for their development until other micro-organisms have time to overcome these inhibiting effects. Once the nitrifiers become established they are able to convert large quantities of ammonia to nitrate and withstand great concentrations of their own product (in spite of the tendency to increase in acidity due to nitric ions). For example, in the Edmonton and Vegreville sterilized re-inoculated soils there was an accumulation of 427 and 470 p.p.m. of nitrate, yet these organisms seem to carry on their work. In the non-sterilized soil, bacteria, fungi, Actinomycetes and to some extent protozoa, are active, feeding on organic matter or its products to obtain food and energy. Proteins, amines and other nitrogenous substances from the organic matter are converted into simpler nitrogen compounds including ammonia and some free nitrogen by a large number of bacteria and fungi, and to a slight extent by

Actinomycetes of the soil. After this first ammonification stage the nitrifying bacteria oxidize the ammonium compounds to nitrous acid and nitrates. As a result the nitrates accumulate in the non-sterilized soil.

In the sterilized soil this biochemical process of breaking down organic matter and converting the ammonia or the ammonium compounds into nitrates has ceased with the destruction of the micro-organisms during sterilization, so that the nitrates remain at the same or even slightly lower level than at the beginning.

In the sterilized soil re-inoculated with the original soil, presumably the same micro-organisms that were present in the non-sterilized soils are active though in small numbers at first. Schreiner and Lathrop (13) found an increase in a large number of nitrogenous compounds following sterilization so that if the micro-organisms in the sterilized re-inoculated soils were as active as in the non-sterilized there should have been greater nitrate accumulation. Table 10 shows that nitrates were depressed until 10 weeks so that we must conclude that sterilization has made the soil, for a time, more toxic to the nitrifying organisms but more favorable afterwards, or else the nitrifying organisms develop slowly in re-inoculated soil as compared to ammonifying organisms.

Table 10 - Nitrification in non-sterilized, sterilized and re-inoculated sterilized Alberta soils.

### Ammonification.

The results of ammonification experiment are shown in table 11 and graphs 10 to 13.

The most vigorous ammonification occurred in the sterilized re-inoculated (with original soil) treatment in every one of the four soils. In the first 4 to 6 weeks of incubation, a steady increase in ammonia took place, rising to a high peak, as may be seen in graphs 10, 11 and 12. This increase was followed by a rapid return to normal at about 12 weeks, from which time the sterilized re-inoculated assumed the same level as the non-sterilized. Fallis soil behaved very differently from the other three soils in that ammonification was very low, and it took a longer time for the sterilized re-inoculated to return to normal.

Soils high in organic matter produced large quantities of ammonia; for example, Edmonton soil 198 p.p.m., Vegreville 172, Gros Ventre 126 and Fallis 63, of ammoniacal nitrogen.

The non-sterilized Edmonton and Vegreville soils, both high in organic matter, showed a small rise in ammonia on 3 to 6 days incubation. This was probably due to moistening and bringing to the optimum conditions of temperature and structure, soils that had been kept air-dry, which renewed the activity of the soil micro-organisms. This slight increase in the first 6 days amounted to approximately 30 and 50 p.p.m. of ammoniacal nitrogen. It soon disappeared as the nitrifiers became active, so that after the first few days ammonia in the non-sterilized treatments remained at a very low level, in the order of 10 p.p.m., until the

Introduction

The purpose of this investigation was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The first part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The second part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The third part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The fourth part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The fifth part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The sixth part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The seventh part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The eighth part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The ninth part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

The tenth part of the experiment was to determine the effect of the amount of water on the growth of the plant. The results of the experiment are shown in Table I.

end of the experiment.

The sterilized soils remained at a fairly constant level, below the re-inoculated but above the non-sterilized. Edmonton sterilized remained at about 80 p.p.m., with one fluctuation when it rose to 125 p.p.m., graph 10; the Vegreville sterilized generally remained slightly lower with two fluctuations up to 85 and 96 p.p.m., graph 11; Gros Ventre about 65 p.p.m., graph 12;, and Fallis soil approximately 35 p.p.m. of ammonia, graph 13.

The larger fluctuations in the sterilized soils, as well as high readings, were probably due to contamination from the air. Although great care was exercised when watering the flasks and precautions were taken to avoid re-infection by using sterile water and sterile pipettes and flaming each flask when the plug was removed, still air contamination could have taken place since each flask was opened every week or ten days and kept opened long enough to add the water from a pipette. Besides that, the cotton plugs soon became loose from cultivating the soil by means of the stirring rod imbedded in each plug.

That sterilization was properly carried out was proved by plating out soils sterilized in flasks as for the experiments with nitrates and ammonia, except that the time of sterilization was reduced to 15 minutes at full pressure. No growth in sterilized soils took place when plated out, using Thornton and Gray's medium. This was repeated and confirmed.

A shorter experiment on ammonification was also set up as a duplication of the longer experiment, and ammonia was determined

and of the experiment.

The sterilized soil remained at a fairly constant level below the re-inoculated but above the non-sterilized. Although sterilized remained at about 50 p.p.m., with the inoculation when it rose to 100 p.p.m., from 10; the degree of fertility was actively remained slightly lower with the inoculation up to 50 and 10 p.p.m., from 10; and from 10 p.p.m., from 10; and falls well approximately 50 p.p.m. in amount, from 10. The lowest fluctuations in the sterilized soils, as well as with the lines, were probably due to contamination from the air. Although these were not reached when watering the lines and precautions were taken to avoid re-inoculation by water, the soil was sterilized by boiling and then when the glass was removed, still its contamination could have been from the air and there was no need of ten days and kept sterile long enough to add the water from a sterile source that the cotton plants soon became free of infection the soil by means of the stirring rod imbedded in each line. That sterilization was properly carried out was proved by placing one sterile sterilized in three for the experiment with nitrites and ammonia, except that the time of sterilization was reduced to 15 minutes at 100 p.p.m. in growth in sterilized soils took place when placed on a sterile surface and kept sterile. This was repeated and confirmed. A further experiment to demonstrate was also run on a duplicate of the former experiment, and ammonia was demonstrated

after 3 and 6 days, 2 weeks and 4 weeks after sterilization. The results of this experiment are not shown in table 11 because the figures show exactly the same trends as those in the first experiment. Much the same quantities of ammonia were found except that Fallis re-inoculated contained a little more at 4 weeks than that shown in table 11 (71 p.p.m. compared to 52 p.p.m. as indicated).

As a comparison with ammonia in the soil under natural conditions, samples of Edmonton soil were brought into the laboratory on October 3, 1937, and ammonia determined at once. Moisture was determined on a separate sample of the same soil. It was found that on that day in the field, Edmonton sod contained 19.5 percent moisture and an average of 8.4 p.p.m. of ammoniacal nitrogen. This, of course, was only a single day's determination, and considerable fluctuation may occur.

Since the method used to determine ammonia involved the use of magnesium oxide to displace the ammonia on distillation, it was thought advisable to find if magnesium oxide would break down dissolved organic matter and liberate ammonia in stages rather than causing it to be given off completely in one stage. On second distillation it was found that a very small amount of ammonia could be obtained from the second distillation. An average of 30 determinations indicates 4 p.p.m. of ammoniacal nitrogen were given off when the second distillation was prolonged for 45 minutes. This indicates that the values obtained in the ammonification experiment are not absolutely quantitative. But since all the distillations were carried out under uniform conditions of distilling for three quarters of an hour from the first boiling, during which time approximately 250 cc. of dis-

tillate were collected, practically all of the ammonia that entered into base exchange or ammonium salts was collected from the first distillation.

#### The Rate at which Ammonia was Distilled.

It was also found that most of the ammonia was distilled over in 15 minutes from the first boiling. In 4 minutes, more than .56 mgms. of ammoniacal nitrogen were distilled. In 7 minutes, 10, 15, 18 and 20 minutes, more than 1.12 mgms., 2.24, 3.36, 3.92 and 4.48 mgms. of ammoniacal nitrogen were distilled over and collected in standard acid. These figures, expressed on the basis of a 25 gram sample as used in most determinations of ammonia (except where the contents were high when a 12.5 gram sample was used instead), would mean that more than 90 p.p.m. of ammonia in 10 minutes, 135 p.p.m. in 15 minutes and 180 p.p.m. in 20 minutes, were distilled over in the first distillation. Therefore, distilling for 45 minutes from the first boil, i.e., one hour from the time the flames were lighted, would allow well over the time required for complete distillation because the highest amount obtained from any soil in the experiment (see table 11) was less than 200 p.p.m.

Ammonification, like nitrification, is a biochemical process, but unlike the latter it can be carried on by a large number of bacteria (*Bacillus mycoides*, *B. mesentericus vulgatus*, etc.) and fungi (as *Mucor*, *Penicillium*, *Rhizopus*, *Trichoderma*, etc.). Organic matter is decomposed by bacteria and fungi and converted to simpler nitrogen compounds and ammonia.

Sterilization partly decomposes organic matter (13) which is more easily attacked than undecomposed organic matter.

filtrate were collected, practically all of the ammonia that entered into these exchanges or ammonia salts was collected from the first distillation.

The date at which ammonia was distilled.

It was also found that most of the ammonia was distilled over in 15 minutes from the first boiling. In 2 minutes, more than .75 mg. of ammonia was distilled. In 7 minutes, 10, 15, 20 and 30 minutes, more than 1.12 mg., 2.25, 3.37, 4.44 mg. of ammonia were distilled respectively. Ammonia was collected in standard cells. These figures, expressed in the form of a 25 gram sample, are in good determination of ammonia (except where the contents were not when a 10% gas sample was used instead), would mean 1.12 mg. from 10 g. of ammonia in 10 minutes, 2.25 mg. in 15 minutes and 3.37 mg. in 20 minutes, were distilled over in the first distillation. Therefore, the first 15 minutes from the first boil, i.e., one hour from the time the flames were lighted, would allow with over the time required for complete distillation because the liquid content obtained from any cell in the first distillation (see table II) was less than 200 g. of ammonia.

Ammonia, like nitric acid, is a typical product of the urine and feces as can be carried on by a large number of bacteria (Bacteria, Bacillus, etc., etc.) and fungi (as yeasts, Penicillium, etc., etc.). It is also present in decomposed animal and plant and associated to various nitrogenous compounds and elements. Ammonia is a typical product of the urine and feces as can be carried on by a large number of bacteria (Bacteria, Bacillus, etc., etc.) and fungi (as yeasts, Penicillium, etc., etc.). It is also present in decomposed animal and plant and associated to various nitrogenous compounds and elements.

The maximum rise in ammonia took place in about 4 weeks, after that it began to decline, while in the case of nitrification the greatest accumulation of nitrates took place at the end of the experiment.

There is an inverse relation between ammonia and nitrate in soil. When the nitrifiers become active they convert ammonia to nitrates and as a consequence ammonia almost disappears while the nitrates accumulate. It should be noted that high nitrification followed high ammonification.

### Sulfofication.

Water soluble sulphates in the three treatments of the four Alberta soils, as affected by sterilization, re-inoculation with the original soil, and incubation, are summarized in table 14.

Generally speaking, there was only a small increase in water soluble sulphates in the non-sterilized soils, with increased period of incubation, but there was a great increase in the sterilized re-inoculated except in the Fallis soil.

Another finding was that sterilization alone considerably increased the sulphate content in each soil as will be noted in the first column of table 14. For example, in the Edmonton soil, sterilization without any subsequent incubation caused an increase of about 25 p.p.m.; in the case of Vegreville soil, 46 p.p.m.; Gros Ventre over 30 p.p.m.; and Fallis about 19 p.p.m. of sulphate.

The non-sterilized treatments increased in water soluble sulphates very slowly during the 12 weeks incubation. Two soils showed hardly any change; Edmonton soil ended up with only 8 p.p.m. more than at the beginning, Vegreville 25 p.p.m., Gros Ventre 38 p.p.m. and Fallis 15 p.p.m. more of sulphate.

The sterilized re-inoculated treatments showed the greatest increases of all the treatments, up to 12 weeks. Those increases were 125 p.p.m., 52 p.p.m., 36 p.p.m. and 2 p.p.m. in Edmonton, Vegreville, Gros Ventre and Fallis soils respectively, over the amounts in the same treatment right after sterilization.

The sterilized showed some fluctuations and the agreement was not as close as could be desired. In two soils, the Gros

Ventre and Fallis, sulphates were almost as high as in the sterilized re-inoculated. This was not anticipated and is hard to explain. There is a possibility that some flasks became contaminated; then there is some variation due to sampling, but it would hardly explain the high results obtained.

In Fallis sterilized soil there was almost no increase in sulphates at the end as compared to the beginning of 12 weeks; in Gros Ventre an increase of 16 p.p.m. as judged by the 12 weeks reading but no increase before this; in Edmonton sterilized 45 p.p.m. or about half of that in the sterilized re-inoculated; and in Vegreville about 30 p.p.m. more than at the beginning.

From the results presented in table 14 it appears that water soluble sulphates are increased by sterilization since greater quantities were found in the sterilized and sterilized re-inoculated than in the non-sterilized soils. (There is one exception, that in Fallis soil at 4 weeks incubation, which no doubt was accidental contamination either when evaporating the extract to dryness or in the electric muffle).

Sterilization, therefore, probably causes the breaking down of sulphur compounds in the soil -- chiefly proteins -- making sulphur more easily oxidizable. How it is changed to sulphate form in the sterilized soil where the action of sulphur oxidizing micro-organisms is excluded would have to be explained possibly on some chemical basis such as oxidation. The apparent increase in sulphate in uninoculated sterilized soil may be due merely to an increase in soluble organic matter which on ignition gives higher sulphate results.

In the sterilized re-inoculated soils the sulphur oxidizing bacteria, probably *Thiobacillus thiooxidans*, *Thiobacillus denitrificans*, *Thiobacillus thioparus*, certain ammonifying bacteria (29) and certain sulphur oxidizing fungi would no doubt be responsible for the higher sulphate accumulation.

Either sterilized soil has been made a more favorable medium for these organisms or sterilization has destroyed some antagonistic organisms which if present in the inoculum take a long time to become active enough to bring about an equilibrium such as that which exists in the non-sterilized soil.

Table 13 shows a comparison of the amount of water soluble sulphate found with and without ignition of the evaporated extracts. It shows that without ignition only about one-half as much sulphate was obtained as with the ignition. It suggests that part of the sulphate obtained with ignition comes from the oxidized organic matter and is therefore not precipitated without ignition.

Table 14 - Sulfification in non-sterilized, sterilized, and reinoculated sterilized Alberta soils.

Ophiobolus.

The results of pure culture experiment with a root rotting fungus, *Ophiobolus*, an antagonistic fungus No. 32, and a non-antagonistic fungus No. 3, are shown in table 15. From the figures obtained so far, it appears that the antagonistic fungus (to *Ophiobolus*) No. 32, was the strongest and the most rapid ammonifier of the three organisms, while the non-antagonistic fungus No. 3, was the weakest and the slowest ammonifier. For example, in 15 days fungus No. 32, produced 169 p.p.m. of ammoniacal nitrogen, while the fungus No. 3, only 76 p.p.m., less than one-half of the former. The same relation holds true at 6 weeks, but at 5 weeks and at 4 weeks the differences were not nearly so great.

Comparing these results with ammonification in Edmonton non-sterilized, sterilized and sterilized re-inoculated with original soils, table 15, shows that there was a greater accumulation of ammonia in each of the pure cultures than in the non-sterilized with two exceptions, when the non-antagonistic pure culture was lower than the sterilized. In pure cultures there was less ammonia accumulated in 15 days than in the sterilized re-inoculated, but after 15 days there was more in the pure cultures.

In the non-sterilized soil, the nitrifiers (*Nitrosomonas* and *Nitrobacter*) were present, converting ammonia into nitrate almost as quickly as it was produced; therefore, ammonia did not accumulate to such an extent as in the pure cultures, where

Discussion

The results of this study are summarized in Table I. The results show that the rate of growth of the plants is significantly higher in the treatment with the highest concentration of the growth hormone than in the other treatments. This is especially evident in the treatment with the highest concentration of the growth hormone, where the rate of growth is significantly higher than in the other treatments. The results also show that the rate of growth is significantly higher in the treatment with the highest concentration of the growth hormone than in the other treatments. This is especially evident in the treatment with the highest concentration of the growth hormone, where the rate of growth is significantly higher than in the other treatments.

the nitrifying organisms were destroyed. In the sterilized soil re-inoculated with original soil, the nitrifiers, killed by sterilization, when introduced again by the inoculum, took some time to become active. Ammonia accumulated at first, but after a few weeks it began to decline; evidently more and more of it was being converted to nitrates. In pure cultures of the three organisms, the nitrifiers were destroyed so that the ammonia was accumulating and not being converted to nitrate.

Possible reasons why fungus No. 32, produced more ammonia than the other two organisms are: Firstly, it may naturally be a stronger ammonifier. Secondly, sterilization may have altered the nature of the soil physically and chemically making it a more favorable medium for this particular fungus.

Table 15 - Ammonification by pure cultures of fungi when inoculated on sterilized soil as compared with ammonification in non-sterilized, sterilized, re-inoculated sterilized Edmonton sod.

### Summary of Results.

A study was made of the effects of steam sterilization and re-inoculation on certain physical, chemical and biological relationships of four Alberta soils.

Mechanical analysis of Edmonton black loam (to silt loam), Vegreville black fine sandy loam, Gros Ventre brown loam and Fallis gray silt loam, did not bring out any significant differences between the sterilized and the non-sterilized soils.

Capillary rise was decreased due to sterilization in the case of the Edmonton soil by 49.3 percent, Vegreville 62.0 percent, Gros Ventre 53.5 percent and Fallis 37.1 percent. Vegreville black soil was most affected and Fallis gray wooded least affected in this respect.

Water holding capacity and the moisture content at the "sticky point" were somewhat lower in the sterilized compared to the non-sterilized soils, but the differences were hardly significant.

There were indications in the Vegreville, Gros Ventre and Fallis soils that the shrinkage in sterilized soils was increased, but the experimental error was as great as the increases. There was no indication of change in the Edmonton soil.

Sterilization did not increase or significantly decrease the pH values of the soils determined one day after sterilization.

The amount of water soluble phosphorus in sterilized soils was increased to about twice the amount in the non-sterilized except in the Fallis soil in which case the increase was much smaller.

Easily soluble phosphorus (soluble at pH 3) was increased by

about one-third on the average in the Edmonton soil and by one-seventh in the Vegreville. However, in the cases of the Fallis gray wooded soil and the Gros Ventre brown prairie soil, the differences were insignificant. Apparently the steam sterilization affects the solubility of phosphorus in soils rich in organic matter to a greater extent than in other soils.

Nitrification was depressed for about 8 to 10 weeks in the sterilized re-inoculated soils but became much more active from 12 to 39 weeks as compared to non-sterilized, especially in soils high in organic matter. The uninoculated sterilized soils maintained a fairly constant level of nitrates throughout the period.

Ammonification in the sterilized re-inoculated soils increased rapidly for 4 weeks in the black Edmonton and Vegreville soils, and for 6 weeks in the brown Gros Ventre soil, then returned to normal in 8 to 12 weeks and remained at about the same level as the non-sterilized until the end of the experiment. Fallis gray wooded soil (low in organic matter) took a long time to reach its maximum and return to normal, although its peak was the lowest of all the soils.

The water soluble sulphate content of the soils was increased immediately following sterilization. There was also some increase in the non-sterilized, sterilized and sterilized re-inoculated soils upon incubation. In the black Edmonton and Vegreville soils the sterilized re-inoculated increased more than the non-sterilized.

Ammonification tests of pure cultures of the root rotting fungus *Ophiobolus*, an antagonistic to *Ophiobolus* fungus No. 32, and a non-antagonistic fungus No. 3, when inoculated into sterilized Edmonton black park soil, showed that the antagonistic fungus No.

32, was the most rapid and the strongest ammonifier, and that the non-antagonistic fungus No. 3, was the slowest and the weakest ammonifier.

Steam sterilization of soils has brought about changes in certain physical, chemical and biological relationships of the four Alberta soils used in this investigation.

1. The first part of the paper is devoted to the study of the asymptotic behavior of the solutions of the system (1) as  $t \rightarrow \infty$ . It is shown that the solutions of the system (1) tend to zero as  $t \rightarrow \infty$  if and only if the matrix  $A$  is Hurwitz. The second part of the paper is devoted to the study of the asymptotic behavior of the solutions of the system (1) as  $t \rightarrow \infty$  if the matrix  $A$  is not Hurwitz. It is shown that the solutions of the system (1) tend to infinity as  $t \rightarrow \infty$  if and only if the matrix  $A$  is not Hurwitz. The third part of the paper is devoted to the study of the asymptotic behavior of the solutions of the system (1) as  $t \rightarrow \infty$  if the matrix  $A$  is not Hurwitz. It is shown that the solutions of the system (1) tend to infinity as  $t \rightarrow \infty$  if and only if the matrix  $A$  is not Hurwitz.

Acknowledgement.

The writer wishes to express his appreciation to Dr. J. D. Newton, under whose supervision this investigation was carried out, and to Dr. F. A. Wyatt, Head of the Department of Soils, for their kindness and willing assistance.

Acknowledgement is also due to Dr. Ignatieff and members of the Department of Soils for their helpful suggestions, and to the National Research Council for the financial assistance which made this investigation possible.
